Abstract

As demand for Real-Time applications rise among the general public, the importance of enabling large-scale, unbound algorithms to solve conventional problems with low to no latency is critical for product viability[8]. Timer algorithms are prevalent in the core mechanisms behind of operating systems[3], network protocol implementation, stream processing, and several database capabilities. This paper presents a field tested algorithm for a low latency, unbound range timer structure, based upon the well excepted Timing Wheel algorithm. Using a set of queues hashed by TTL, the algorithm allows for a simpler implementation, minimal overhead no overflow and no performance degradation in comparison to the current state of the algorithms under typical use cases.
Index Terms - Stream Processing, Timing Wheel, Dehydrator, Callout facilities, protocol implementations, Timers, Timer Facilities.

1 Introduction

2 Model

In similar manner to previous work[9][7][5], the model discussed in this paper shall consist of the following components, each corresponding with a different stage in the life cycle of a timer in the data store:

$$StartTimer$$
$$\downarrow$$
$$PerTickBookkeeping \circlearrowleft$$
$$\swarrow \qquad \searrow$$
$$DeleteTimer \qquad TimerExpired$$

StartTimer(TTL,timerId{,Payload}): This routine is called by the client to start a timer that will expire in after the TTL has passed. The client is also expected to supply a *timer ID* in order to distinguish it from other timers in the data store. Some implementations also allow the client to provide a *Payload*, usually some form of a callback action to be performed or data to be returned on timer expiration.

PerTickBookkeeping(): This routine encompasses all the actions, operation and callbacks to be performed as part of timer management and expiration check every interval as determined by the data store granularity. Upon discovery of an outstanding timer to expire *TimerExpired* will be initiated by this routine.

DeleteTimer(timerId): The client may call this utility routine in order to remove from the data store an outstanding timer (corresponding with a given *timer ID*), this is done by calling *TimerExpired* for the requested timer before *PerTickBookkeeping* had marked it to be expired.

TimerExpired(timerId): Internally invoked by either *PerTickBookkeeping* or *DeleteTimer* this routine entails all actions and operations needed in order to remove all traces of the timer corresponding with a given *timer ID* from the data store and invoking the any callbacks that were provided as *Payload* during the *StartTimer* routine.

Since payload and callback behavior varies significantly between different data store implementations, the store of such data can be achieved for $O(1)$ using a simple hash map, and the handling of such callbacks can be done in a discrete, highly (or even embarrassingly) parallel this paper will disregard this aspect of timer stores.

3   Current Solutions

3.1   Lists, Queues & Hash Maps

Being included as an integral part of almost any modern programming language, these basic data structures enable convenient and simple addition of timer management to any software. That said, such simple structures suffer from oversimplification and are appropriate for very unique use cases - where the number of timers it fairly small or the ticks are far enough from one another. Using such implementations for large scale applications will require the grouping of timer producers and consumers into groups small

Operation	List/Queue	Hash Map
StartTimer	$O(log(n))$	$O(1)$
PerTick	$O(1)$	$O(n)$
DeleteTimer	$O(n)$	$O(1)$
TimerExpired	$O(1)$	$O(1)$

Table 1: Mean Runtime Complexity for timing schemes based on common data structures

3.2   Hashed Timing Wheel

The Hashed Timing Wheel was designed to be an all purpose timer storage solution for a unified system of known size and resolution[10][9][11]. While previous work have shown that Hashed Timing

Wheels have optimal run-time complexity, and in ideal conditions are in fact, optimal, real-world implementations would suffer from either being bound by maximal TTL and resolution combination, or would require a costly ($O(n)$) run-time re-build upon of the data structure upon reaching such limits (in [7] it is referred to as "the overflow problem"). For large numbers of timers, producers, or consumers as is common in large scale operations, the solution is commonly to over estimate the needed resolution and/or TTL so to abstain from rebuilding for as long as possible.

Operation	Worst	Mean
StartTimer	$O(1)$	$O(1)$
PerTick	$O(n)$	$O(1)$
DeleteTimer	$O(1)$	$O(1)$
TimerExpired	$O(1)$	$O(1)$

Table 2: Runtime Complexity for the Hashed Timing Wheel scheme

4   The Lawn Data Structure

4.1   Intended Use Cases

This algorithm was first developed during the writing of a large scale, Stream Processing geographic intersection product using a FastData[6] model. The data structure was to receive inputs from one or more systems that make use of a very limited range of TTLs in proportion to the number of concurrent timers they use.

Assumptions and Constraints : As this algorithm was designed to operate as the core of a dehydration utility for a single FastData application, where TTLs are usually discrete and variance is low it is intended for use under the assumptions that:

$$Unique\ TTL\ Count \ll Concurrent\ Timer\ Count$$

Assuming that most timers will have a TTL from within a small set of options will enable the application of the core concept behind the algorithm - TTL bucketing.

4.1.1 The Data Structure

Lawn is, in it's core, a hash of sorted sets[1], much like Timing Wheel. The main difference is the key used for hashing these sets is the timer TTL. Meaning different timers will be stored in the same set based only on their TTL regardless of arrival time. Within each set the timers are naturally sorted by time of arrival - effectively using the set as a queue. Using this queuing methodology based on TTL, we ensure that whenever a new timer is added to a queue, every other timer that is already there should be expired before the current one, since it is already in the queue and have the same TTL.

The data structure is analogous to blades of grass (hence the name) - each blade grows from the roots up, and periodically (in our case every $Tick$) the overgrown tops of the grass blades (the expired timers) are maintained by mewing the lawn to a desired level (current time).

4.2 Algorithm

4.2.1 Correctness

To prove correctness of the algorithm, it should be demonstrated that for each Timer, it is expired (by the calling the $TimerExpired$ operation or it) within $Tick$ of it's intended TTL. As the algorithm pivots around the TTL bucketing concept, where in each timer is stored exactly once in it's corresponding bucket, and these buckets are independent of each other, it is sufficient to demonstrating correctness for all timers of a bucket, That is:

$$\forall \quad T^{start}, T^{ttl} \in \mathbb{N} \quad \exists \quad T^{stop} \in \mathbb{N} :$$
$$T^{stop} - T^{start} \approx T^{ttl}$$

Alternatively, we can use the sorting analogy made by G. Varghese et al.[9] to show that given two triggers T_n, T_m:

$$\forall \quad T_n, T_m \quad | \quad T_n^{start} < T_m^{start}, T_n^{ttl} = T_m^{ttl} \quad \exists \quad T_n^{stop}, T_m^{stop} \Rightarrow T_n^{stop} < T_m^{stop}$$

Taking into account that each bucket only contains triggers with the same TTL we can simplify the above:

$$\forall \quad T_n, T_m \quad | \quad T_n^{start} < T_m^{start} \Rightarrow T_n^{stop} < T_m^{stop}$$

---
[1]These are the TTL 'buckets'

Algorithm 1 The Lawn Data Store

Precondition:
1: id - a unique identifier of a timer.
2: ttl - a whole product of $TickResolution$ representing the amount of time to wait before triggering the given timer $payload$ action.
3: $payload$ - the action to perform upon timer expiration.
4: $current\ time$ - the local time of the system as a whole product of $TickResolution$

5: **function** INITLAWN()
6:     TTLHash ← new empty hash set
7:     TimerHash ← new empty hash set
8:     $closest\ expiration \leftarrow 0$

9: **function** STARTTIMER($id, ttl, payload$)
10:     $endtime \leftarrow$ current time $+ ttl$
11:     $T \leftarrow (endtime, ttl, id, payload)$
12:     TimerHash$[id] \leftarrow T$
13:     **if** $ttl \notin$ TTLHash **then**
14:         TTLHash$[ttl] \leftarrow$ new empty queue
15:     TTLHash$[ttl]$.**insert**(T)
16:     **if** $endtime < closest\ expiration$ **then**
17:         $closest\ expiration \leftarrow endtime$

18: **function** PERTICKBOOKKEEPING()
19:     **if** current time $< closest\ expiration$ **then**
20:         **return**
21:     **for** $queue \in$ TTLHash **do**
22:         $T \leftarrow$ **peek**($queue$)
23:         **while** $T_{endtime} <$ current time **do**
24:             **TimerExpired**(T_{id})
25:             $T \leftarrow$ **peek**($queue$)
26:         **if** $closest\ expiration = 0$
    or $T_{endtime} < closest\ expiration$ **then**
27:             $closest\ expiration \leftarrow T_{endtime}$

28: **function** TIMEREXPIRED(id)
29:     $T \leftarrow$ TimerHash$[id]$
30:     **DeleteTimer**(T)
31:     **do** $T_{payload}$

32: **function** DELETETIMER(id)
33:     $T \leftarrow$ TimerHash$[id]$
34:     **if** $T_{endtime} = closest\ expiration$ **then**
35:         $closest\ expiration \leftarrow 0$
36:     TTLHash$[T_{ttl}]$.**remove**(T)
37:     TimerHash.**remove**(T)
38:     **if** TTLHash$[T_{ttl}]$ is empty **then**
39:         TTLHash.**remove**$[ttl]$

Which, due to the bucket being a sorted set, ordered by T^{start} and triggers being expired by bucket order from old to new is self-evident, and we arrived at a proof.

4.2.2 Space and Runtime Complexity

The Lawn data structure is dense by design, as every timer is stored exactly once, a new trigger will add at most a single TTL bucket and empty TTL buckets are always removed, the data structure footprint will only grow linearly with the number of timers. Hence, overall space complexity is linear to the number of timers ($O(n)$).

Operation	Worst	Mean
$StartTimer$	$O(1)$	$O(1)$
$PerTick$	$O(n)$	$O(t \sim 1)$
$DeleteTimer$	$O(1)$	$O(1)$
$TimerExpired$	$O(1)$	$O(1)$

Table 3: Runtime Complexity for the Lawn scheme

Since the *PerTickBookkeeping* routine of Lawn iterates over the top item of all known TTL buckets on every expiration cycle (where at least one timer is expected to expire), it's mean case runtime is linear to t (the number of different TTLs) and seems to be lacking even in comparison to more primitive implementations of timer storage. That said, with an added assumption that the TTL set size is roughly constant over time, or at worst asymptotically smaller then the number of timers, we can regard this operation as constant time.

This assumption is valid in our case as it is derived from the needs of the algorithm users, these being other computer systems, which often have either a single TTL used repeatedly, their TTLs chosen from a list of hard coded values or derived from a simple mathematical operation (sliding windows are a good example of this method, using fixed increments or powers of 2 to determine TTLs etc.). Computer systems which are using highly variable TTL values are suitable for usage with this timer algorithm only under specific circumstances (such as multi-worker expiration system as described below).

Space complexity is $O(n)$ since at worst case each timer is stored in its own bucket alongside a single entry in the timer hash. To compare, this spatial footprint is bound from above by that of the Hashed Hierarchical Time Wheel, as due to it's multi-level structure a single timer can be pointed at by a chain of hierarchical wheels, increasing its overall space requirement.

5 Comparison and Reflection

Designed for large scale, high throughput systems, Lawn has displayed beyond state of the art performance for systems complying with its core assumptions of multi worker, hi-frequency, hi-timer-count with low TTL variance applications.

5.0.1 An Algorithmic View of Multiprocessing

Unlike the state-of-the-art Timer Wheel algorithm, Lawn enables the simultaneous timer handling and bookkeeping by splitting the buckets between several worker processes/threads, adding or removing workers as needed. This method enables the usage of the Lawn algorithm in highly parallel applications and does not requires a use of semaphores than other synchronization mechanisms within the bucket level.

6 Conclusion

XXXXXXX

6.0.1 Known implementations of Lawn in the wild

1. Redis Internals [4] - a high performance in memory key value store - uses Lawn implementation for streams and other internal timers.

2. Mellanox RDMA timers for the Infiniband switching system[1].

3. User specific rate limiting timers for client device power consumption optimization[2].
